Abstract

The absorption of oxygen in aqueous–organic solvent emulsions was studied in a laboratory-scale bubble reactor at a constant gas flow rate. The organic and the gas phases were dispersed in the continuous aqueous phase. Volumetric mass transfer coefficients (kL a) of oxygen between air and water were measured experimentally using a dynamic method. It was assumed that the gas phase contacts preferentially the water phase. It was found that addition of silicone oils hinders oxygen mass transfer compared to air–water systems whereas the addition of decane, hexadecane and perfluorocarbon PFC40 has no significant influence. By and large, the results show that, for experimental conditions (organic liquid hold-up ≤ 10% and solubility ratio ≤ 10), the kL a values of oxygen determined in binary air–water systems can be used for multiphase (gas–liquid–liquid) reactor design with applications in environmental protection (water and air treatment processes).

1. Introduction

Recent developments in bioreactor design have attempted to address some of the limitations of existing bioreactors. However, further progress in innovative bioreactor design remains a high priority, particularly for: (i) environmental bioreactors and (ii) increases in oxygen transfer from the gas phase to the microorganisms. In both cases, the addition of an organic solvent to the aqueous phase can be used to improve the efficiency of the bioprocess [1,2].

The development of environmental bioreactors is important for waste gas purification and treatment because polluted air has become of growing environmental and health concern. Recent papers have demonstrated that biological techniques often offer a cost-effective and environmentally friendly alternative to conventional air pollutant control technologies, such as catalytic oxidation or incineration [3–6]. Studies carried out in our laboratory have demonstrated the ability of bioscrubbing to deodorize waste gases and remove volatile organic compounds (VOC) from an air stream [7]. However, conventional bioscrubbers can only be used for compounds that are readily soluble in water. For waste gases containing hydrophobic compounds having low solubility in water, the efficiency of the biological treatment is limited by the poor mass transfer of the pollutant from the gas phase to the aqueous phase. To overcome this problem, a multiphase bioscrubber was developed using a mixture of a non-biodegradable organic solvent and water to enable the absorption of the hydrophobic pollutant in an absorber (gas–liquid–liquid contactor). The water–solvent emulsion, with the absorbed pollutants mainly in the organic phase, is then transported to a bioreactor in which microorganisms degrade the pollutant dissolved in the aqueous phase. The lower pollutant concentration in the aqueous phase resulting from this process is the driving force for pollutant diffusion from the organic to the aqueous phase (Fig. 1). Thus, complete biological regeneration of the liquid is possible [8]. Numerous applications for the biodegradation of toxic and poorly water-soluble compounds improved by organic liquids have been described by Déziel et al. [9]. In addition, it is assumed that the organic solvent would enhance the oxygen mass transfer from the gas phase to the microorganisms in order to improve the degradation of the pollutant. Such a potential increase in the oxygen mass transfer due to the presence of organic solvent is also taken into account for the development of oxygen-limited bioreactors, as in the case of the microbial fermentation.
Nomenclature

- $a$: interfacial area (m$^{-1}$)
- $C_{\text{org}}$: oxygen concentration in organic solvent (mol m$^{-3}$)
- $C_{\text{water}}$: oxygen concentration in water (mol m$^{-3}$)
- $C_{\text{gas}}$: equilibrium concentration of oxygen between water and gas phase (mol m$^{-3}$)
- $D$: diffusion coefficient (m$^2$ s$^{-1}$)
- $H$: Henry constant (Pa m$^3$ mol$^{-1}$)
- $k$: mass transfer coefficient (m s$^{-1}$)
- $k_{\text{L},a}$: volumetric mass transfer coefficient (s$^{-1}$)
- $m_{\text{org}}$: solubility ratio
- $p_{\text{oxygen}}$: partial pressure of oxygen in the gas phase (Pa)
- $P$: total pressure of the gas phase (Pa)
- $Q_G$: gas flow rate (m$^3$ s$^{-1}$)
- $R$: universal gas constant (J mol$^{-1}$ K$^{-1}$)
- $T$: temperature (K)
- $u_G$: gas velocity (m s$^{-1}$)
- $V_G$: volume of the gas phase (m$^3$)
- $V_L$: volume of the liquid phase (m$^3$)
- $y_{\text{oxygen}}$: oxygen mole fraction

Greek letters

- $\varepsilon$: energy dissipation (W kg$^{-1}$)
- $\mu$: dynamic viscosity (Pa s)
- $\rho$: density (kg m$^{-3}$)
- $\sigma$: surface tension (N m$^{-1}$)
- $\phi$: dispersed liquid phase hold-up

of products of commercial interest. Organic solvents would act as surface-active agents to lower the surface tension of water and increase the gaseous specific interfacial area. However, to date, the transfer mechanism of oxygen is not well understood and it is not possible to propose a unified theory to describe satisfactorily the effect of the presence of organic solvent on the enhancement of the mass transfer of oxygen [10].

As oxygen mass transfer has a strong influence on bioprocess efficiency, we carried out experiments with a view to measuring, by a dynamic method, the volumetric mass transfer coefficient ($k_{\text{L},a}$) of oxygen in emulsions of water–organic solvent for the main organic liquids used in bioprocesses, i.e. dodecane, hexadecane, perfluorocarbons and silicone oils. Table 1 presents examples of organic solvents used in biological waste air treatment or to improve microbial production or fermentation. Experiments were carried out in a bubble column with the organic and gas phases dispersed in the continuous aqueous phase. This multiphase system represents the most unfavourable one for oxygen mass transfer because it is assumed that there is no contact between the gas phase and the organic phase.

2. Materials and methods

2.1. Chemicals

Dodecane and hexadecane were obtained from the Sigma–Aldrich Company. Perfluorocarbon PFC40 Fluorinert (primarily compounds with 12 carbons) was purchased from the 3M Company and silicone oils (Rhodorsil® fluids 47V5 and 47V10, dimethylpolysiloxane) were purchased from the Rhodia Company. The physical properties of these chemical products are summarized in Table 2. Spreading coefficients were obtained from Hassan and Robinson [47] for dodecane and hexadecane, from MacMillan and Wang [48] for PFC40, and from Basheva et al. [49] for silicone oil 47V5. Solubility ratios $m_{\text{org}}$ (i.e. solubility of oxygen in organic liquid divided by solubility of oxygen in water) were obtained from Vadekar [50] for dodecane and hexadecane, from van Sonsbeek et al. [51] for PFC40, and from Dumont et al. [52] for silicone oils.

2.2. Equipment

A dynamic method, extensively described in [53], was used to determine the volumetric mass transfer coefficients of oxygen during absorption. In this method, a known gas volume, initially loaded with 20.9% oxygen, was continuously flowed via a circulating loop through the deoxygenated liquid system. The operation was batch wise with respect to the liquid system and the decrease in oxygen concentration in the gas phase was measured versus time. A schematic overview of the experimental set up is given in Fig. 2. The reactor used has an 11.5 L total volume (height 0.33 m, diameter 0.21 m). In the experiments, air was supplied from a compressor and sparged through an elliptical distributor (75 mm × 150 mm) with 50 holes (1 mm diameter). The superficial velocity of gas ($u_G$) was 0.01 m s$^{-1}$ (gas flow rate $Q_G = 3.3 \times 10^{-4}$ m$^3$ s$^{-1}$). All experiments were carried out, as presented in [53], at a constant temperature of 20 °C maintained by the jacket. The total volumes of gas and liquid were 2 and 10 L, respectively.

3. $k_{L}a$ calculation

3.1 Assumptions

The dynamic method for $k_{L}a$ measurement in air–water–oil systems is based on the gas phase mass balance and on the off-gas analysis technique, which has been proved to be a relevant measurement method [54–56]. $k_{L}a$ measurement is supported by some assumptions:

1. In the reactor, the ideal gas law is applicable to calculate the number of moles of oxygen absorbed by the liquid. The
operating conditions justify such an assumption, since temperature and pressure are low.

2. The resistance of oxygen transfer in the gas phase is neglected, which is nearly always permitted [57]. Thus, the overall mass transfer coefficient is considered as the liquid phase mass transfer coefficient $k_{La}$.

3. The liquid phase can be reasonably estimated as perfectly mixed. This may be assumed considering the convective recirculation and turbulence caused by the rising gas bubbles leading to a much shorter mixing time than the characteristic mass transfer time, $1/k_{La}$.

4. The gas phase is considered as plug flow in the closed flowing circuit as in the oxygen analyser circuit.

5. The presence of an organic solvent in the emulsion does not change the Henry constant for oxygen in water.

6. There is no contact between the gas and the organic liquid phase.

7. As liquid–liquid mass transfer is very fast compared to gas–liquid mass transfer, a liquid–liquid equilibrium in terms of oxygen concentration can be assumed during oxygen absorption.

8. The response time for the paramagnetic oxygen analyser is less than 5 s, which is less than the mass transfer response time of the system: $1/k_{La}$.

3.2. Derivation of $k_{La}$

In the system including three phases, the total change in concentration of oxygen in air $C_{gas}$ is due to the amount of oxygen absorbed in the water phase (continuous liquid phase) and to the amount of oxygen absorbed in the organic phase (dispersed liquid phase):

$$-V_G \frac{dC_{gas}}{dt} = V_L (1 - \phi) \frac{dC_{water}}{dt} + V_L \phi \frac{dC_{org}}{dt}$$  \hspace{1cm} (1)$$

$V_L$ is the total volume of the liquid phase and $V_G$ is the total volume of the gas phase. $C_{water}$ and $C_{org}$ are the concentrations of oxygen in water and organic phases, respectively. $\phi$ is the dispersed liquid phase hold-up (volume of organic liquid phase as a fraction of total liquid phase volume).

As the water phase and the organic phase are assumed to be in equilibrium at any time (assumption 7):

$$C_{org} = m_R C_{water}$$  \hspace{1cm} (2)$$

$m_R$ is the solubility ratio defined as the ratio of the solubility of oxygen in the organic phase to that in water. Oxygen dissolves much better in organic solvents than in water (Table 2).

Eqs. (1) and (2) lead to:

$$-\frac{dC_{gas}}{dt} = \frac{V_L}{V_G} \left(1 + \phi (m_R - 1)\right) \frac{dC_{water}}{dt}$$  \hspace{1cm} (3)$$

The oxygen concentration in the constant volume of gas is obtained from mass balance:

$$C_{gas} = \frac{P}{RT} y_{oxygen}$$  \hspace{1cm} (4)$$

where $y_{oxygen}$ is the mole fraction of oxygen in the gas phase and $P$ is the total pressure in the gas phase considered constant during the experiment. After differentiating with respect to time $t$, Eq. (5) is obtained from Eq. (4):

$$\frac{dC_{gas}}{dt} = \frac{P}{RT} \frac{d y_{oxygen}}{dt}$$  \hspace{1cm} (5)$$

Combining Eqs. (5) and (3) gives, after integrating between $t = 0$ ($C_{water} = 0$ and $y_{oxygen} = y_{oxygen}(t=0)$) and $t$.

$$C_{water} = -\frac{V_G}{V_L} \left(1 + \phi (m_R - 1)\right) \frac{P}{RT} (y_{oxygen}(t) - y_{oxygen}(t=0))$$  \hspace{1cm} (6)$$

According to assumptions 3 (liquid phase perfectly mixed) and 6 (no contact between the gas and the organic phase), the mass transfer rate in the gas liquid system is given by:

$$-V_G \frac{P}{RT} \frac{d y_{oxygen}}{dt} = k_{La} V_L \left(C_{water}^{*} - C_{water}\right)$$  \hspace{1cm} (7)$$

$k_{La}$ is based on the total volume of the liquid (aqueous and organic phases) instead of the aqueous volume to avoid an appar-
ent increase in value solely due to a decrease in the aqueous phase volume. $C_{\text{water}}^*$ is the equilibrium concentration between water and the absorbed gas phase. $C_{\text{water}}^*$ is defined according to Eq. (8), where $p_{\text{oxygen}}$ is the partial pressure of oxygen in the gas phase and $H$ is the Henry constant for oxygen in water:

$$C_{\text{water}}^* = \frac{p_{\text{oxygen}}}{H}$$

Dividing by the total pressure $P$, Eq. (8) becomes:

$$C_{\text{water}}^* = \frac{p_{\text{oxygen}}}{P}$$

Introducing the expression of $C_{\text{water}}$ and $C_{\text{water}}^*$ in Eq. (7) gives:

$$-\frac{V_G}{V_L} \frac{RT}{d} \frac{d y_{\text{oxygen}}}{d t} = k_L a \left[ \frac{P H y_{\text{oxygen}}}{1 + \phi (m R - 1)} + \frac{V_G}{V_L} \frac{1}{1 + \phi (m R - 1)} \right]$$

whose integration between $t = 0$ and $t$ gives:

$$\frac{1}{\alpha + (1/(1 + \phi (m R - 1)))} \ln \left[ \frac{y_{\text{oxygen}}(t)}{y_{\text{oxygen}}(0)} \right] = k_L a t$$

with $\alpha = \frac{V_G RT}{V_L a}$. By plotting the left-hand side of Eq. (11) versus time, we obtained a straight line whose slope gives the volumetric mass transfer coefficient $k_L a$ for the aqueous phase in the presence of organic phase. Introducing $\phi = 0$ in Eq. (11) allows the determination of $k_L a$ in a binary air–water system.

4. Experimental results and discussion

Binary air–water system: 39 measurements were carried out. For each experiment, the decrease in the mole fraction of oxygen ($y_{\text{oxygen}}$) in the gas phase versus time was recorded. The determination of $k_L a$ from experimental data was then obtained by using Eq. (11). Typical representations of $k_L a$ determinations have previously been published [52,53]. For our apparatus and the hydrodynamic conditions ($u_G = 0.01 \text{ms}^{-1}$), $k_L a$ values ranged from 0.0132 to 0.0178 s$^{-1}$ (mean value $k_L a = 0.0156$ s$^{-1}$; standard deviation 15%; grey zone in Fig. 3).

Air–water–organic phase: experiments were carried out in triplicate using several emulsion compositions, varying from 0 to 4% for PFC40 and from 0 to 10% for silicone oils, dodecane and hexadecane. Fig. 3 presents the $k_L a$ results for all organic solvents (maximum deviation: ±15%) compared with those obtained for an air–water system without an organic phase in the same hydrodynamic conditions. Addition of silicone oils hinders the volumetric mass transfer coefficient of oxygen compared to air–water systems. The effects are greater for the most viscous silicone oil (47V10). Decreases in $k_L a$ of up to 25% are noted. Conversely, taking into account the accuracy of measurement, Fig. 3 shows that organic phase addition has no significant influence on $k_L a$ results in the cases of dodecane, hexadecane and perfluorocarbon PFC40. In the latter case, the high density (1850 kg m$^{-3}$) of the organic phase leads to a specific behaviour.
of the liquid phase. Whereas bubbling leads to oil droplet formation in the continuous water phase for organic phases lighter than water, PFC40 settles at the bottom of the reactor for all the amounts added. In this case, the perfluorocarbon remains under the gas distributor and it is not possible to disturb it sufficiently to disperse droplets in the bulk of the water. However, the interface between the organic phase and water is continuously moved by the recirculating flow of water in the reactor. Due to the absence of droplets and the non-miscibility of PFC40 in water, it could be assumed that the organic phase does not influence the hydrodynamic conditions and the interfacial area, which is consistent with the experimental $k_{ad}$ measurements. MacMillan and Wang [48], measuring the air bubble size distribution by a photographic method, showed that the interfacial area in PFC40 dispersions was independent of PFC loading from 0 to 15% (v/v). Similar method, showed that the interfacial area in PFC40 dispersions [48], measuring the air bubble size distribution by a photographic method, showed that the interfacial area in PFC40 dispersions was independent of PFC loading from 0 to 15% (v/v).

Considering the influence of organic phase addition on $k_{ad}$ only, contrasting results have been reported in the literature. In a review devoted to gas absorption in oil-in-water systems, Dumont and Delmas [10] reported that the $k_{ad}$ value can decrease, remain unaffected or increase upon addition of the organic phase. For instance, Hassan and Robinson [47] found, for the same experimental conditions, that hexadecane addition increases $k_{ad}$ whereas dodocane addition decreases $k_{ad}$. Unfortunately, these authors were not able to explain these opposing results. To date, a satisfactory assessment of the influence of the addition of small amounts of organic phase on the mass transfer of oxygen remains difficult. Nonetheless, a recent model has been proposed [58]. This model takes both shuttle effects and hydrodynamic effects into account to calculate the enhancement factor due to the presence of the organic liquid droplets. The general expression of this model is:

$$\frac{k_{ad} \phi}{k_{ad,0}} = \left( \frac{D_{\phi}}{D_{\phi,0}} \right)^{1/2} \left( \frac{\mu_{\phi,0} \phi}{\mu_{\phi} \phi_{c,0}} \right)^{1/4}$$  \hspace{1cm} (12)

The first term of the right-hand side expression represents the influence of the shuttle effect on the enhancement; the second represents the hydrodynamic effect. $D$ is the diffusion coefficient of oxygen, $\mu$ the dynamic viscosity of the emulsion, $\rho$ the density of the emulsion and $\epsilon$ corresponds to the energy dissipation rate of the system. $\phi = 0$ and $\phi$ correspond to the binary air–water system and multiphase system, respectively. An assessment of the influence of the shuttle effect is difficult to calculate. For our system ($\phi \leq 0.1$ and $n_{<} < 10$) and, according to Fig. 4 from [58], the shuttle effect should range from 1 to 1.2. For the hydrodynamic effect, the energy dissipation rate is assumed unchanged between each experiment. Thus, the change in $k_{ad}$ is due only to the change in the density and the dynamic viscosity of the emulsion with the addition of oil. Calculations of $\mu_2$ and $\mu_3$ are detailed in [58]. According to Eq. (12) and the data gathered in Table 2, it appears that the hydrodynamic effect ranges from 1 to 0.95 when $\phi$ varies from 0 to 10%. Finally, the modelled $k_{ad}$ values calculated for all organic phases ($0 \leq \phi \leq 0.1$), and taking into account both shuttle and hydrodynamic effects, are within the maximum deviation of the experimental results.

As demonstrated experimentally, the addition of an organic phase has no significant positive influence on the volumetric mass transfer coefficient of oxygen for our experimental conditions. The results obtained could be explained by the interfacial properties of the emulsions, particularly by the spreading coefficient defined as:

$$S = \sigma_{AW} - \sigma_{OW} - \sigma_{OA}$$  \hspace{1cm} (13)

where $\sigma$ are interfacial tensions and the subscripts AW, OW and OA refer to air–water, oil–water and oil–air interfaces, respectively. A positive value of $S$ is corresponded to correspond to easy spreading of the oil droplet on gas bubbles. For dodocane and hexadecane, $S$ is negative (Table 2), which implies that the organic solvent remains as discrete droplets and does not contact the gas bubbles. In both cases, the transfer is not affected by the presence of organic droplets and $k_{ad}$ remains roughly constant. For silicone oils, $S$ is “initially” positive (Table 2; $S$ is calculated with the values of pure component surface tension), which implies that these organic phases should be able to spread on the gas–aqueous surface. However, when the aqueous and organic phases are mutually saturated, Basheva et al. [49,59] have demonstrated that $S$ becomes negative at equilibrium ($S = -0.8 \text{ mN m}^{-1}$ for silicone oil whose viscosity is $5 \text{ mPa s}$), which ultimately implies that silicone oil remains as discrete droplets. Morao et al. [60], who found similar changes in $k_{ad}$ with silicone oil addition, discussed the influence of silicone oil on both $k_{ad}$ and $a$. According to these authors, silicone oil, acting as an antifoam agent, has two opposing effects on the interfacial area $a$. On the one hand, silicone oil lowers the surface tension between gas and liquid, thus decreasing the bubble diameter and consequently increasing $a$. On the other hand, silicone oil tends to promote coalescence, thus decreasing $a$. Morao et al. [60] and Kawase and Moo-Young [61] suggested that these opposing effects more or less cancel each other out, and hence the most important effect is on the film coefficient $k_{ad}$. According to [60], the variation in the relative $k_{ad}$ measurements (decreasing then increasing with oil addition, Fig. 3) can be explained by three effects; as oil concentration increases, (i) bubble surface mobility decreases, (ii) coalescence is enhanced and (iii) surface tension decreases. The first two effects, which depress $k_{ad}$, may however reach a limit, namely when all contacting bubbles coalesce and mobility is suppressed. Meanwhile, surface tension keeps decreasing, reducing bubble size, and hence $k_{ad}$ starts to rise. According to this explanation, there is a critical concentration at which the gas–liquid mass transfer is minimal.

While contradictory results exist about the actual mechanisms of mass transfer in gas–water–organic systems [10], it seems that the relationship between the mass transfer coefficient $k_{ad}$ and the physical–chemical properties of the emulsion are not sufficiently taken into account and should be reconsidered.

In summary, it appears that the use of an organic phase is a good strategy for enhancing the productivity of cultures by microorganisms or allowing the biodegradation of gaseous hydrophobic pollutants, whatever the bioreactor design. Firstly, the organic phase acts as an oxygen reservoir, increasing the oxygen driving force between the air and the water–oil emul-
sion and allowing the enhancement of the oxygen uptake rate from the air to the microorganisms. Several positive results have been reported from the literature for all the organic phases used: hexadecane [2,22,23]; dodecane [15–17]; perfluorocarbons [1,2,15,30,31]; concerning the use of silicone oils, the used: hexadecane [2,22,23]; dodecane [15–17]; perfluorocarbon PFC40 has no significant influence. The negative influence of silicone oil addition on the oxygen uptake rate is nonetheless reduced as soon as the amount added is more than 5%. By and large, the addition of a non-biodegradable organic solvent, acting as an oxygen reservoir and/or a substrate reservoir, improves the efficiency of bioprocesses. Thus, the addition of decane, hexadecane and perfluorocarbon PFC40 dispersed in the aqueous phase. Addition of silicone oils hinders the mass transfer enhancement by oxygen carriers in the autotrophic cultivation of Alcaligenes eutrophus under lower oxygen partial pressure, J. Chem. Eng. Jpn. 28 (1995) 218–220.

5. Conclusion

Volumetric mass transfer coefficients \( k_{L}a \) of oxygen between air and water in different gas–aqueous–organic phase systems have been measured experimentally using a dynamic method. Experiments were carried out in the most unfavourable multiphase system for oxygen mass transfer (organic phase dispersed in the aqueous phase). Addition of silicone oils hinders oxygen mass transfer compared to air–water systems whereas the addition of decane, hexadecane and perfluorocarbon PFC40 has no significant influence. The negative influence of silicone oil addition on the oxygen uptake rate is nonetheless reduced as soon as the amount added is more than 5%. By and large, the addition of a non-biodegradable organic solvent, acting as an oxygen reservoir and/or a substrate reservoir, improves the efficiency of bioprocesses. For our experimental conditions (organic liquid hold-up \( ≤ 10\% \) and solubility ratio \( ≤ 10\) ), the \( k_{L}a \) values of oxygen determined in binary air–water systems can be used in multiphase (gas–liquid–liquid) reactor design.
